Data Driven Calibration and Control of Compact Lightweight Series Elastic Actuators for Robotic Exoskeleton Gloves

Yunfei Guo, Wenda Xu, Sarthark Pradhan, Cesar Bravo, and Pinhas Ben-Tzvi, Senior Member, IEEE

Abstract—The working principle of a SEA is based on using an elastic material connected serially to the mechanical power source to simulate the dynamic behavior of a human muscle. Due to weight and size limitations of a wearable robotic exoskeleton, the hardware design of the SEA is limited. Compact and lightweight SEAs usually have noisy signal output, and can easily be deformed. This paper uses a compact lightweight SEA designed for exoskeleton gloves to demonstrate immeasurable strain and friction force which can cause an average of 34.31% and maximum of 44.7% difference in force measurement on such SEAs. This paper proposes two data driven machine learning methods to accurately calibrate and control SEAs. The multi-layer perception (MLP) method can reduce the average force measurement error to 10.18% and maximum error to 29.13%. The surface fitting method (SF) method can reduce the average force measurement error to 8.06% and maximum error to 35.72%. In control experiments, the weighted MLP method achieves an average of 0.21N force control difference, and the SF method achieves an average of 0.29N force control difference on the finger tips of the exoskeleton glove.

Index Terms—Tactile sensor, SEA calibration, exoskeleton glove.

I. INTRODUCTION

A. Exoskeleton and Tactile Sensors

CLOSE to 19.9 million people in the U.S. suffer from hand-related disabilities and have difficulty grasping objects for day-to-day activities [1]. Building an affordable robotic exoskeleton glove that can help these individuals perform grasping-related tasks regularly encountered in their daily lives could significantly improve their quality of life.

Lee designed and integrated the iSAFER glove using rigid linkage and cable transmission with two force-sensitive resistors (FSR) on both the fingernail and finger pad side to adapt to the contact angle change [2]. However, FSRs suffer from issues related to repeatability [3]. There are over ±50% errors on random raw data of FSR force sensors.

Ma, et al. designed a robotic exoskeleton glove using rigid actuators and side-mounted strain gauges as a tactile sensor to perform force control [4]. The advantages of using strain gauges include comfort and their compact size. However, this method requires calibration for each user to achieve an accurate result.

Diez, et al. proposed a novel design of a robotic exoskeleton using an optical force sensor as a tactile sensor, which resolved the accuracy problem when using FSRs [5]. This approach could be a great solution, except that the sensor’s size is too large for an exoskeleton glove application.

B. Series Elastic Actuators

Using Series Elastic Actuators (SEA) may be a practical option for a high accuracy exoskeleton glove after reviewing the previous methods. The original SEA design was proposed...
by the MIT Artificial Intelligence Laboratory in 1995 [6]. In the original design, a torsion spring is connected in series between the output shaft of an electric motor and the SEA output shaft. The output force is calculated by measuring the angle of twist in the torsion spring. Compared to rigid actuators, advantages of using SEAs include accurate force sensing and wider control bandwidth. Springs provide more linear and repeatable force-sensing than FSRs. Springs can also act as low-pass filters to filter out the high-frequency motion, reducing the control speed leading to wider control bandwidth. The structure and force calculation of SEAs is explained in Fig. 1. Following the original SEA design, a wide variety of SEAs have been used in robotic exoskeletons. Kim, et al. designed hydraulic SEAs to be used in exoskeleton assisted walking, and sit-to-stand (SIT) motions [7]. Karavas, et al. designed electric SEAs for joints used in lower limber exoskeletons [8]. Those designs provide accurate force control and high output force. However, those designs required large hydraulic or electric power sources with metal housings and output shafts. The main challenges of applying the SEAs mentioned above to a robotic exoskeleton glove are the size and weight.

Work done in previous research built several lightweight, compact SEAs for robotic exoskeleton gloves to reduce the size and weight. The primary purpose of using SEAs on an exoskeleton glove is as tactile sensors to provide accurate force measuring. Proper force measuring on fingertips using SEAs requires high rigidity of the elastic material’s exoskeleton and low stiffness. High rigidity usually leads to bulky designs, and low stiffness will restrict the maximum output force. Most of the previous research either suffered from inaccurate force feedback due to the deformation of the exoskeleton or deficient force output that cannot fulfill user needs.

Force calibration is essential for performing force feedback control with SEAs. The feedback control will not work without calculating the correct amount of force generated by the SEA.

This paper proposes a method to calibrate and design a control scheme for compact, lightweight SEAs using multi-layer perception (MLP). Implementing the MLP method is then compared against those found using a surface fitting (SF) approach, which is considered a commonly used technique. After calibration, these SEAs can be used as accurate tactile sensors on a robotic exoskeleton glove. The calibration meth-
Fig. 3. The construction of the SEA and exoskeleton used in this research.

Agarwal, et al. designed a cable-driven exoskeleton with rigid linkage using two SEAs on each finger [9]. This previous design is shown in sub-figure A of Fig. 2. Force control used in this previous research has about 10% error and can output 0.3Nm peak torque on each SEA output joint. The main issues with this design are the size and weight. To output 0.3Nm torque to one finger requires the use of two large RE-Max 29 motors. The user needs to carry the power source (motor, motor pulley, battery), which dramatically reduces mobility.

Jo, et al. designed a compact linear SEA for use in robotic exoskeleton gloves [11]. This design is shown in sub-figure C of Fig. 2. Accurate force control is achieved with a linear-quadratic (LQ) tuned proportional-derivative (PD) controller to control the distance and a disturbance observer (DOB) to model the uncertainty. However, the spring constant is very low (0.343 N/mm), which results in a maximum output force of 9N to the SEA output shaft. In contrast, a normal healthy 20-29-year-old male can output a maximum of 450N on all fingers, which is about 90N on each fingertip [14].

Refour et al. designed a compact linear SEA for robotic exoskeleton gloves, which can output 20N on each fingertip [12]. This design is shown in sub-figure D of Fig. 2. One of the main issues with this design is force accuracy. According to the author, the SEA experiences 2-3N of output force error. This error is measured at the SEA output shaft, which does not include the error caused by the linkage mechanism itself. Due to the unaccounted deformation of the plastic SEA housing and thin aluminum linkage, the force output on the fingertips may be inaccurate. Because of the inaccuracy in force output on the fingertips, it may not be effective to sacrifice the SEA’s space over FSRs.

Xu, et al. proposed a low-cost, compact, lightweight SEA used in the RML exoskeleton [13]. This design is shown in sub-figure E of Fig. 2. The SEA has a high force output of 40N at the SEA output shaft and 20N at each fingertip. This size is desirable for exoskeleton applications. However, this SEA suffered from rigidity and accuracy problems which affected many of the other designs discussed previously. It uses thin aluminum linkages with 3D printed plastic motor output shafts and housing. Due to the high output and low rigidity, the linkage motor output shaft on the SEA will deform. This deformation causes the force output of the SEA to be non-linear in relation to the strain of the elastic material in the SEA.

III. SEA FORCE MODELING

This paper uses the SEA design presented in Xu, et al.’s paper [13] as an example. This SEA is compact, lightweight, low-cost, and provides sufficient force output (Maximum 20N on fingertips). However, it exhibits noisy sensor reading, hard-to-measure friction force, a back drive-able motor, and deformable linkages and SEA housing. These characteristics make this SEA a good candidate to demonstrate the difficulty of using traditional kinematics model-based calibration. The SEA and exoskeleton overview is shown in 3. The index finger SEA is used as an example to demonstrate the force calculation.

A. Series Elastic (SEA) Actuator Construction

The compact, lightweight SEA built for the RML glove consists of a linear actuator and a linkage. Force on the fingertips can be measured when these two parts are combined. The first part is a regular elastic linear actuator with motor, gearbox, lead crew, lead nut, spring, and output shaft. The second part is an aluminum linkage that transfer force from the linear actuator’s output shaft to the fingertips. Both parts are described in the linear SEA portion of Fig. 3.

B. SEA Force Calculation

The index finger SEA is showed in Fig. 4. Theoretically, when the SEA is not moving, the force can be calculated by Eq. 1. The encoder can sense the distance between DE and the potentiometer can sense $\Delta ABC$. CB and CE are constant and can be directly measured. $\delta l_s$ can be calculated by Eq. 2. $F_{fa}$ and $F_{fl}$ can be compensated for with a constant value during force calibration. $R_l$ is a variable that changes as the linkage angle changes. The ratio varies for different force measuring methods. This ratio is discussed in the following section.

$$F_i = (\delta l_s \times k_s - F_{fa}) \times R_l - F_{fl} \tag{1}$$

$$\delta l_s = \cos(2\Delta ABC) \times CB - (DE - CE) \tag{2}$$
\[ F_t \] — force on linkage tip, perpendicular to the last linkage
\[ \delta_l \] — spring compression
\[ F_{fa} \] — friction force of actuator
\[ R_l \] — SEA to linkage force transformation ratio
\[ F_{fl} \] — friction force of linkage

C. Encoder

A 12 CPR Pololu quadrature magnetic encoder is attached to a 12v Pololu micro-gear motor paired with a 380:1 gearbox. The lead screw has a distance (mm) to revolution ratio of 20:1. The actuator shaft movement \( \delta DE \) in millimeters can be calculated by Eq.3.

\[
\delta DE = \frac{R_{ld}}{N_{cpr}} \times \frac{20}{12} \times N_{enc} \\
\approx 0.00438596 \times N_{enc}
\]

\( \delta DE \) — displacement of DE measured in millimeters
\( R_{ld} \) — distance to revolution ratio of lead screw, 20mm:
1rev
\( R_g \) — output shaft to input shaft ratio of gearbox, 380:1
\( N_{cpr} \) — count per revolution of encoder, 12
\( N_{enc} \) — encoder count

D. Angular Potentiometer

A 15 to 345-degree angular potentiometer is placed on the linkage to measure the linkage angle. Such potentiometer is read through a 3.3v 12 bit ADC bus. This potentiometer’s voltage is increased to 20.5v for better resolution. Due to the voltage, the effective range can be calculated using Eq.4. A 20 degrees mechanical offset is introduced to avoid over-voltage damage to the micro-controller. \( \angle ABC \) is calculated by Eq.5.

\[
E R_{pot} = \frac{V_{ad}c}{V_s} \times R_{pot} = \frac{3.3}{20.5} \times 330^\circ \approx 53.12195^\circ
\]

\[
\angle ABC = \frac{E R_{pot}}{R_{adc}} \times P_{ot} - \angle O + \angle S
\]

\( E R_{pot} \) — effective measuring range of potentiometer
\( V_{adc} \) — adc bus reference voltage, 3.3v
\( V_s \) — source voltage of potentiometer, 20.5v
\( R_{pot} \) — measuring range of potentiometer, 330 degrees
\( R_{adc} \) — adc resolution, 12bit, 4096
\( P_{ot} \) — raw potentiometer adc reading
\( \angle O \) — potentiometer offset angle, 20 degrees
\( \angle S \) — potentiometer start angle, 15 degrees

E. Force Measurement

Force measurement is usually performed using a load cell. However, measuring force directly from the linkage end can be complicated as it is difficult to place the load cell perpendicular to the last linkage. In this research, the force is measured by two different load cells placed at a different location to accommodate the linkage at different angles. The mounting position is shown in Fig. 5. The force measured at the linkage end is transformed back to the actuator output shaft through inverse kinematics.

F. Linkage Force Transformation Ratio

The linkage design is based on [15]’s optimization. The linkages force transformation ratio \( R_l \) is critical for calculating the fingertips’ force. When the last linkage’s contact angle
is less than 90 degrees, the load cell is mounted horizontally. When the last linkage’s contact angle is more than 90 degrees, the load cell is mounted vertically. The relationship between angle and the linkage force transformation ratio ($R_l$) is shown in Fig. 6. The horizontal linkage force transformation ratio is described as a fifth-order equation ($H_{fit}$), and the vertical linkage force transformation ratio is described as a second-order equation ($V_{fit}$). The combined equation is shown in Eq. 6.

$$R_l = \begin{cases} H_{fit} & \text{if } 5^\circ \leq \angle ABC \leq 16^\circ \\ V_{fit} & \text{if } 16^\circ < \angle ABC \leq 28^\circ \end{cases}$$

(6)

IV. CHALLENGES WITH SEA FORCE CALIBRATION

Based on the previous section, the force output of the SEA should be easy to calculate. PID position control is used to drive the SEA. The calculated force is compared with the measured force from a load cell.

Theoretically, the measured force and calculated force should be similar. However, when testing the SEA, the measured force and calculated force have up to around 45% difference in value. There exist two major problems that the previous research has not addressed: friction and deformation, which are discussed in the following subsections.

A. Friction Force on the Actuator

The spring constant of the spring used in this SEA is 4.2 N/mm. Using the traditional SEA force calculation that the previous researchers used, the output force should match the calculated force without the linkage affecting it. However, the experimental result in Fig. 7 showed that the measured force was generally lower than the calculated force because there exists a large amount of frictional force that affects the output force.

B. Combined Friction Force of the Linkage and the Actuator

The friction force has a significant impact on the output force. This experiment is to find the combined friction force caused by the linkage and the actuator. During this experiment, the SEA with the linkage is actuated against a load cell at various angles. The measured compression from the SEA will increase, but the load cell’s reading remains zero. The load cell’s reading will not be zero when the applied force is greater than friction force, and the measured compression represents the amount of friction force. Fig. 8 shows that the friction force varies at different angles.

C. Actuator Shaft and Linkage Deformation

Theoretically, if the friction force is calibrated at a different angle, the commanded output force should match the measured force. However, the measured force was still significantly smaller than the commanded force.

The difference is due to two parts on the SEA deforming when force is applied. The resulting strain reduces the force output to the fingertips. In Fig. 9 part A, the actuator output force is measured without the linkage attached. The encoder reading remains the same, but the force starts to decrease. In part B, the calculated force is calibrated for the measured friction force. However, there exists over 48% difference.
A. Multi-Layer Perception Approach Force Predictor

A multi-layer perception model is used to predict the output force based on the sensor reading. The network is shown in 10. Except for the friction force and deformation of the actuator shaft and linkage, the model will also take acceleration and speed into consideration. The friction force has a different direction while moving, and might be different under different speeds and accelerations. Thus, the network has nine inputs, including the raw potentiometer reading, the raw encoder reading, the calculated spring compression, and the above variables’ speeds and accelerations.

B. Network Tuning and Lost Function Selection

The calibration network is adjusted using hyper-parameter tuning. The hyper-parameter tuning is focused on finding the best layer, number of nodes, and cost function combination. Two standard cost functions are compared.

The mean absolute error (MAE) is shown in Eq. 7. The error measures the absolute difference between the prediction and measured value. This case, the difference means the difference in force.

$$E = \frac{1}{n} \sum_{j=1}^{n} |y_j - \hat{y}_j|$$  \hspace{1cm} (7)

The mean squared error (MSE) is shown in Eq. 8. The error measures the square of the difference between the prediction and measured value. This method punished outlier data more than the MAE error.

$$E = \frac{1}{n} \sum_{j=1}^{n} (y_j - \hat{y}_j)^2$$  \hspace{1cm} (8)

VI. FORCE CONTROL

When controlling the SEA, traditional force feedback control will not work well due to the low control frequency. In a compact design mentioned in Xu et al.’s [13] paper, the onboard micro-controllers run ten threads and control seven different SEAs, which means it does not have the computational power to run the prediction network. Cloud computing is required for prediction networks, but the delay in cloud computing restricts the control speed. The control frequency is set to 10Hz due to the limitation of wireless connection over Bluetooth. The control is divided into two parts: A high-level spring compression predictor based on force sensor readings and a low-level compression controller.
A. Low-Level Control Method and Control Margin

The low-level PID spring compression control runs on the micro-controller. This low-level controller can ensure accurate control of the spring compression and SEA position. This low-level controller is also used as a safety feature to ensure that the motor works correctly even when the wireless connection is cut off.

The SEA used in this research has a noisy sensor reading due to an analog sensor. The reference voltage fluctuates a little bit, causing a loud sensor reading. Using a noisy angular potentiometer directly as the low-level control input will cause the compression reading to oscillate as the potentiometer reading fluctuates.

The DC motor used in this research has a maximum speed of 32,300 RPM with a low-resolution 12-bit CPR encoder attached to the motor shaft. Twenty encoder counts are equivalent to 0.1 mm in linear actuation. A 0.1 mm difference is equivalent to around 0.5N output force from the actuator output shaft. The requirement of accuracy in motor control is very high.

The position control of the motor is separated from the potentiometer reading to solve the fluctuating sensor reading. The control structure is described in Fig. 12. The PID motor position control runs at 100Hz to ensure accuracy, while the averaged potentiometer reading is updated at 10Hz. The control margin is set to 0.1mm compression difference to avoid oscillation.

B. High Level Multi-Layer Perception Compression Predictor

This compression predictor is modified based on the force calibration network. The network has seven inputs, including the raw potentiometer reading, the raw encoder reading, compression, the speeds and accelerations of the above variables, and the desired force. The network is trained using the same data used for calibration and is tuned using a hyperparameter tuning method. This network can predict the desired compression based on the current data. However, due to the different linkage angles and friction force, the predicted data is not accurate. New data is fed into the predictor to update the predicted compression. The desired compression is sent to the low-level compression controller to perform accurate compression control.

C. Weighted Input Compression Predictor

In the real world, these input data fields do not weigh equally. The desired force has a more significant impact on the compression, and the angle and SEA travel distance have less impact. The acceleration and speed have a low effect on the compression. The input can be weighted to increase the accuracy and robustness of the model. The weight of each factor can be taken as a tuning parameter.

VII. SURFACE FITTING

To compare the performance of the multi-layer perception (MLP) approach, a commonly used, low computational
A. Calibration
For calibration, the inputs are angle and compression, and the result will be the output force. The advantage of this approach is the low computational cost. This method is suitable for calibrating multiple SEAs in parallel on one microcontroller. The disadvantage is that the speed and acceleration are not taken into consideration which might affect accuracy. When moving in different directions, the friction force also acts in different directions. This method does not consider friction force direction. This method does not use as much computational power as the MLP approach by having fewer inputs and only third-order linear regression. As a trade-off, the accuracy might be lower.

B. Control
For controlling the SEA, this method can be used as a direct substitute for the high-level multi-layer perception approach, while the low-level control remains the same. Instead of running on a separate computer and sending results back to the microcontroller through a wireless connection, this method can run on the microcontroller itself.

VIII. Experiments and Results
A. Data Preparation
The data is collected using a load cell. As described in the previous force measurement section, two load cells measure force in different directions, and as such there are two different reference force values based on two different directions. The measured data must be pre-processed to be suitable for training. We transform the force at the fingertip back to the SEA output shaft using the linkage transformation ratio. The force at the SEA output shaft is used as the reference value. This value includes the deformation of the linkage, SEA output shaft, and friction force. Using this model, we can assume that the system is ideal where no friction and deformation need to be considered.

For example, the force output of a SEA is 10N, while 5N of that is lost in transmission. Thus, the net output force is 5N. After calibration, the result will show that the output is 5N, and it can be assumed that there is no loss in force transmission to the fingertip.

The data set used for training contains 10,400 data points, and the test data has 2,416 data points collected using two load cells. Both the test and training data-set include data collected from 12 different contact angles. We have also collected validation data-set at a randomly selected angle with 140 data points to verify the performance.

B. Force Calibration Results
The surface fitting (SF) model is shown in Fig.13. The fitting used a 3rd order polynomial, and most points are fitted to the surface. This graph shows that the force output is not entirely repeatable. There exists a small amount of error in the force output, even with similar angles and compression.

For multi-layer perception approach (MLP), the hyperparameter tuning result of each loss function is shown in Tab. I. For the mean absolute error (MAE) loss function, the optimal network has three layers, and each layer has 8,16,32 nodes. For the mean square error (MSE) loss function, the optimal network has two layers, and each layer has 16,32 nodes.

The result of the multi-layer perception (MLP) model is compared with the surface fitting (SF) method over the testing data-set. The results are shown in Tab. I. For the mean absolute error (MAE) loss function, the optimal network has three layers, and each layer has 8,16,32 nodes. For the mean square error (MSE) loss function, the optimal network has two layers, and each layer has 16,32 nodes.

The result of the multi-layer perception (MLP) model is compared with the surface fitting (SF) method over the testing data-set. The results are shown in Tab. I. For the MLP method, using MSE loss function has 22% performance gain over the SF method. When using MAE loss function, the SF is 72.5% more accurate. The MSE loss function of MLP and MAE of SF is selected to do further comparison.

Fig.14 shows a demo of the force prediction using the above two methods over validation data-set. The MLP method using MSE loss function has a better fit under 15N, while the surface fitting has a better fit over 15N.

### C. Force Control Results

The surface fitting model is shown in Fig.15. The fitting used 3rd order polynomial, and most points are fitted on the surface. This model describes the relationship between compression, force, and angle.

The weighted MLP approach result is shown in Tab. III. For the MAE loss function, the optimal network consists of two layers, and each layer has 8,16 nodes. For the MSE loss function, the optimal network consists of two layers, and each layer has 8,16 nodes.

The weighted multi-layer perception model result is compared with the surface fitting method’s result over the testing data-set. The results are shown in Tab. III. For the weighted MLP method, using both MAE and MSE loss function gives better accuracy than the SF method. Weighted MLP method using MSE loss function has 51.4% perform gain over the surface fitting method using MSE loss function. The MLP method using the MAE loss function has a 20.9% performance gain over the SF method using MAE loss function. Thus, we select MSE as the optimal loss function due to higher performance gain over SF method. MAE loss function is selected for SF method due to less performance difference compare to weighted MLP method.

Fig. 16 shows a simulation of force control using the validation data-set with the above two methods. This simulation used measured force to predict the desired compression and compared the predicted compression with the measured compression. The MLP method has a better fit for low compression, while the SF method fits better under higher compression.

Fig. 17 shows the weighted MLP prediction control performance vs. the surface fitting control in the real world. The tests are performed at 10 degrees. The output force on the SEA output shaft is set to 5N, 10N, and 15N. The
desired force on the fingertip is calculated through the linkage transformation ratio. The actual applied force is measured using a load cell. The result shows that the MLP approach has a slightly more accurate force output. The MLP approach has an error within 0.3N, while the SF method has an error within 0.6N. These experiments show that the force control worked as expected when applied to real hardware.

The settling time increases as the output force increases due to longer actuation time. Each control method is used to output 5/10/15N force at ten different contact angles. The linkage starting angle will be at 5 degrees. The settling time is measured when the linkage comes in contact with the load cell and ends when the output reaches 0.3N and 0.6N error bound. The settling time and force error for different angles is averaged and shown in Tab.II.

The force control curve is not so smooth as expected due to the angle measured by the potentiometer being slightly larger than the actual value due to the moving motor’s voltage drop. It takes time to drop back to a stable reading and this causes a fluctuation in the reading.

**IX. Conclusion**

This paper proposed two methods to control and calibrate a compact, lightweight linear SEA used in an exoskeleton.

This paper showed that friction force and linkage deformation can cause an average of 34.31%, and a maximum of 44.7% difference in force measurement on the compact, lightweight SEA used in the RML glove. These findings can be applied to most exoskeleton gloves that require force transformation from the SEA to the fingertips. Calibration is necessary for any compact, lightweight SEA used in an exoskeleton glove. This paper proposed two methods for calibration and control of the compact, lightweight SEA.

In calibration test, when using MSE loss function and the test data-set, the MLP method is 22% more accurate. When using MAE loss function, the SF is 72.5% more accurate. When the test is conducted using the validation data-set, both methods show similar performance. MLP method has a slightly higher average difference but smaller maximum difference. Both methods are over 65% more accurate than kinematics calculation calibration. The performance comparison of both method on validation data-set is showed in Tab.IV.

In force control test, the MLP method is more accurate using both MAE and MSE loss function. When using MSE loss function, MLP method is 51.4% more accurate. When using MAE loss function, MLP method is 29.1% more accurate. When tested using a validation data-set, MLP method has a slightly higher average difference but smaller maximum difference. In real world testing with the SEA hardware, the MLP method shows 27.5% less average force error than the SF method. However, SF method costs 84.6% less average settling time than the MLP method. The surface fitting approach can run on a micro-controller due to its simplicity. The performance comparison of both methods on validation data-set is showed in Tab.V.

Both methods have decent accuracy and acceptable settling time. For applications which do not require low settling time and have ample computational power, the MLP approach is slightly more accurate. The surface fitting method is suitable for micro-controller applications, where computational power is limited. The surface fitting method is also ideal for application where controlling speed is critical.

**X. Future Work**

There are three aspects of this research that can be further improved.

First, a high dimension non-linear fit might have a more accurate result over the linear surface fitting approach. This approach might not be as accurate compared to the MLP approach but might be faster.

Second, the training data-set only had around 10,000 data points, which is considered a relatively small data-set. The size of the data-set might affect the MLP approach. Extending the data-set might further improve the accuracy of both surface fitting and MLP approaches.

Third, this experiment proved that the SEA-based exoskeleton glove needs calibration to achieve a reasonable force measurement result. The error arises when force is transformed from the spring to the fingertips. Unlike most SEA applications used in upper and lower limbs, the SEAs and linkage used in exoskeleton gloves are usually made from plastic or aluminum due to weight and size constraints. The above limitations make these linkages and SEAs easy to deform and affect the accuracy of the force output. These errors are hard to overcome. To solve this issue, Chinpon, et al. and Park, et al. proposed and verified a possible optical fiber solution to substitute the SEA as an accurate tactile sensor [16], [17]. The optical fiber approach seems to have high accuracy while remaining small in size.
